Cerebral Angiography

Cerebral angiography uses a catheter, x-ray imaging guidance and an injection of contrast material to examine blood vessels in the brain for abnormalities such as aneurysms and disease such as atherosclerosis (plaque). The use of a catheter makes it possible to combine diagnosis and treatment in a single procedure. Cerebral angiography produces very detailed, clear and accurate pictures of blood vessels in the brain and may eliminate the need for surgery.

Your doctor will instruct you on how to prepare, including any changes to your medication schedule. Tell your doctor if there’s a possibility you are pregnant and discuss any recent illnesses, medical conditions, medications you’re taking and allergies, especially to iodinated contrast materials. If you’re breastfeeding, ask your doctor how to proceed. If you are to be sedated, you may be told not to eat or drink anything for four to eight hours before your procedure. Also, you should plan to have someone drive you home. Leave jewelry at home and wear loose, comfortable clothing. You will be asked to wear a gown.

What is Cerebral Angiography

Angiography is a minimally invasive medical test that uses x-rays and an iodine-containing contrast material to produce pictures of blood vessels in the brain.

In cerebral angiography, a thin plastic tube called a catheter is inserted into an artery in the leg or arm through a small incision in the skin. Using x-ray guidance, the catheter is navigated to the area being examined. Once there, contrast material is injected through the tube and images are captured using ionizing radiation (x-rays).

Cerebral angiography is also called intra-arterial digital subtraction angiography (IADSA). This phrase refers to acquiring the images electronically, rather than with x-ray film. The images are electronically manipulated so that the overlying bone of the skull, normally obscuring the vessels, is removed from the image resulting in the remaining vessels being clearly seen.
What are some common uses of the procedure?

Physicians use the procedure to detect or confirm abnormalities within the blood vessels in the brain, including:

- an aneurysm, a bulge or sac that develops in an artery due to weakness of the arterial wall.
- atherosclerosis, a narrowing of the arteries.
- arteriovenous malformation, a tangle of dilated blood vessels that disrupts normal blood flow in the brain.
- vasculitis, an inflammation of the blood vessels, generally narrowing them.
- a brain tumor.
- a blood clot.
- a tear in the wall of an artery, known as a vascular dissection.
- a stroke.

A cerebral angiogram may be performed:

- to evaluate arteries of the head and neck before surgery.
- to provide additional information on abnormalities seen on MRI or CT of the head, such as the blood supply to a tumor.
- to prepare for other medical treatment, such as in the surgical removal of a tumor.
- in preparation for minimally invasive treatment of a vessel abnormality.

The procedure may also be used to help diagnose the cause of symptoms, such as:

- severe headaches
- slurred speech
- dizziness
- blurred or double vision
- weakness or numbness
- loss of coordination or balance.

How should I prepare?

You should report to your doctor all medications that you are taking, including herbal supplements, and if you have any allergies, especially to local anesthetic medications, general anesthesia or to contrast materials containing iodine (sometimes referred to as "dye" or "x-ray dye"). Your physician may advise you to stop taking aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs) or blood thinners for a specified period of time before your procedure.

Also inform your doctor about recent illnesses or other medical conditions.

If you are going to be given a sedative during the procedure, you may be asked not to eat or drink anything for four to eight hours before your exam. If so, you should have a relative or friend accompany
you and drive you home afterward.

For more information about sedation, visit the Anesthesia page.

You will receive specific instructions on how to prepare, including any changes that need to be made to your regular medication schedule.

You will likely be instructed not to eat or drink anything after midnight before your procedure. Your doctor will tell you which medications you may take in the morning.

Women should always inform their physician and x-ray technologist if there is any possibility that they are pregnant. Many imaging tests are not performed during pregnancy so as not to expose the fetus to radiation. If an x-ray is necessary, precautions will be taken to minimize radiation exposure to the baby. See the Safety page for more information about pregnancy and x-rays.

If you are breastfeeding at the time of the exam, you should ask your radiologist how to proceed. It may help to pump breast milk ahead of time and keep it on hand for use after contrast material has cleared from your body, about 24 hours after the test.

**What does the equipment look like?**

In this procedure, x-ray equipment will be used.

A catheter is a long, thin plastic tube that is considerably smaller than a "pencil lead", or approximately 1/8 inch in diameter.

A catheter is inserted by a radiologist, usually through a tiny hole made by a needle in an artery in the groin. Using x-ray guidance, it is painlessly guided through the body to various vessels in the neck that supply blood to the brain.

Other equipment that may be used during the procedure includes an intravenous line (IV), ultrasound machine and devices that monitor your heart beat and blood pressure.

**How does the procedure work?**

X-rays are a form of radiation like light or radio waves. X-rays pass through most objects, including the body. Once it is carefully aimed at the part of the body being examined, an x-ray machine produces a small burst of radiation that passes through the body, recording an image on photographic film or a special detector.

Different parts of the body absorb the x-rays in varying degrees. Dense bone absorbs much of the radiation while soft tissue, such as muscle, fat and organs, allow more of the x-rays to pass through them. As a result, bones appear white on the x-ray, soft tissue shows up in shades of gray and air appears black.

Until recently, x-ray images were maintained on large film sheets (much like a large photographic negative). Today, most images are digital files that are stored electronically. These stored images are
easily accessible and are frequently compared to current x-ray images for diagnosis and disease management.

Fluoroscopy uses a continuous or pulsed x-ray beam to create a sequence of images that are projected onto a fluorescent screen, or television-like monitor. When used with a contrast material, which clearly defines the area being examined by making it appear dark (or by electronically reversing the image contrast to white), this special x-ray technique makes it possible for the physician to view joints or internal organs in motion. Still images or movies are also captured and stored electronically on a computer.

How is the procedure performed?

This procedure is often done on an outpatient basis. However, some patients may require admission following the procedure. Please consult with your physician as to whether or not you will be admitted.

Prior to your procedure, your blood may be tested to determine how well your kidneys are functioning and whether your blood clots normally.

Because the cerebral angiogram and recovery period may last for several hours, you will be asked to empty your bladder before the procedure begins.

A nurse or technologist will insert an intravenous (IV) line into a vein in your hand or arm so that sedative medication can be given intravenously. Moderate sedation may be used. As an alternative, you may receive general anesthesia.

In children up to mid-teens, cerebral angiography is usually performed with the patient under general anesthesia.

Devices to monitor your heart rate and blood pressure will be attached to your body.

You will be positioned on the examining table.

Your head will be held in place using a strap, tape or a foam head holder so you cannot move it during the procedure.

The area of your body where the catheter is to be inserted will be sterilized and covered with a surgical drape.

Your physician will numb the area with a local anesthetic.

A very small skin incision is made at the site.

Using x-ray-guidance, a catheter (a long, thin, hollow plastic tube) is inserted into a blood vessel through a tiny hole made by a needle and directed to the area to be examined.

The contrast material is then injected through the catheter. A special machine, called a power injector, is used to deliver the contrast material at a precise rate and volume. The injector is attached to the catheter for this purpose. When the contrast material reaches the blood vessels being examined, several sets of x-rays will be taken.
At the end of the procedure, the catheter will be removed and pressure will be applied to stop any bleeding. The opening in the skin is then covered with a dressing. No sutures are needed.

Your intravenous line will be removed.

The procedure is usually completed within one to three hours. Additional time may be required for exam preparation, setup and post-procedure care.

What will I experience during and after the procedure?

You will feel a slight pin prick when the needle is inserted into your vein for the intravenous line (IV) and when the local anesthetic is injected. Most of the sensation is at the skin incision site which is numbed using local anesthetic. You may feel pressure when the catheter is inserted into the vein or artery.

If the procedure is done with sedation, the intravenous (IV) sedative will make you feel relaxed, sleepy and comfortable for the procedure. You may or may not remain awake, depending on how deeply you are sedated.

You may feel slight pressure when the catheter is inserted, but no serious discomfort.

As the contrast material passes through your body, you may experience a warm feeling which quickly subsides.

You will be asked to remain very still while the x-ray images are taken.

The most difficult part of the procedure may be lying flat for several hours.

Once the procedure is complete, the catheter will be removed by the radiologist. Pressure is immediately applied to the puncture site to ensure there is no bleeding. The pressure may be either applied by hand or with a special clamp. In either case, it takes about 10 minutes for the tiny hole in the artery to close.

You will remain in the recovery room for observation for a few hours following the procedure before you return home.

If the catheter was placed in the groin area, you will be given specific instructions regarding how long you may need to keep your leg straight. This will vary based on the technique used to repair the hole created in order to insert the catheter. You may apply ice to the site where the catheter was inserted to relieve pain and swelling.

You may resume your normal diet immediately after the exam. You will be able to resume all other normal activities eight to 12 hours after the exam.

You should report to your physician immediately if you experience any of the following after your procedure:

- weakness or numbness in the muscles of your face, arms or legs
- slurred speech
- vision problems
Who interprets the results and how do I get them?

A radiologist, a physician specifically trained to perform, supervise and interpret radiology examinations, will analyze the images and send a signed report to your primary care or referring physician, who will share the results with you.

Follow-up examinations may be necessary. Your doctor will explain the exact reason why another exam is requested. Sometimes a follow-up exam is done because a potential abnormality needs further evaluation with additional views or a special imaging technique. A follow-up examination may also be necessary so that any change in a known abnormality can be monitored over time. Follow-up examinations are sometimes the best way to see if treatment is working or if a finding is stable or changed over time.

What are the benefits vs. risks?

Benefits

- Angiography may eliminate the need for surgery. If surgery remains necessary, it can be performed more accurately.
- Cerebral angiography presents a very detailed, clear and accurate picture of blood vessels in the brain. This is especially helpful when a surgical procedure or other treatment is being considered.
- Results from cerebral angiography are more accurate than those produced by carotid Doppler ultrasound or other noninvasive imaging of the blood vessels.
- Use of a catheter makes it possible to combine diagnosis and treatment in a single procedure.
- No radiation remains in a patient's body after an x-ray examination.
- X-rays usually have no side effects in the typical diagnostic range for this exam.

Risks

- There is always a slight chance of cancer from excessive exposure to radiation. However, the benefit of an accurate diagnosis far outweighs the risk.
- There is a very slight risk of an allergic reaction if contrast material is injected.
- If you have a history of allergy to x-ray contrast material, your radiologist may advise that you take special medication for 24 hours before cerebral angiography to lessen the risk of allergic reaction. However, the risk of an allergic reaction from contrast material injected into an artery is less than if it is introduced into a vein.
Women should always inform their physician or x-ray technologist if there is any possibility that they are pregnant. See the Safety page for more information about pregnancy and x-rays.

Nursing mothers should wait for 24 hours after contrast material injection before resuming breastfeeding.

The risk of serious allergic reaction to contrast materials that contain iodine is extremely rare, and radiology departments are well equipped to deal with them.

If you have diabetes or kidney disease, the kidneys may be injured due to the contrast material. In most cases, the kidneys will regain their normal function within five to seven days.

Any procedure that involves placement of a catheter inside a blood vessel carries certain risks. These risks include damage to the blood vessel, bruising or bleeding at the puncture site, and infection. However, precaution is taken to mitigate these risks.

There is a small risk that blood will form a clot around the tip of the catheter, blocking the artery and making it necessary to operate to reopen the vessel.

There is a risk of stroke with this procedure if the catheter dislodges plaque from a vessel wall that blocks blood flow within the brain. Although stroke may be a complication associated with cerebral angiography, it is uncommon.

Rarely, the catheter punctures the artery, causing internal bleeding. It is also possible that the catheter tip will separate material from the inner lining of the artery, causing a block downstream in the blood vessel. Given that children do not usually have plaque in their arteries, they would not be as susceptible as adults to have such a complication.

**A Word About Minimizing Radiation Exposure**

Special care is taken during x-ray examinations to use the lowest radiation dose possible while producing the best images for evaluation. National and international radiology protection organizations continually review and update the technique standards used by radiology professionals.

Modern x-ray systems have very controlled x-ray beams and dose control methods to minimize stray (scatter) radiation. This ensures that those parts of a patient's body not being imaged receive minimal radiation exposure.

When performing cerebral angiography in children or young adults, care is often taken to minimize radiation to the ovaries and testes by placing a lead drape under the pelvis.

**What are the limitations of Cerebral Angiography?**

Patients with impaired kidney function may not be good candidates for this procedure.

Patients who have previously had allergic reactions to iodine-containing x-ray contrast materials are at risk of having a second reaction to similar contrast agents.
